Abstract

For transport aircraft, the primary control objective for an autopilot system engaged during approach and landing is relative to the flight-path tracking on the basis of highly simplified linear models of flight dynamics. The dynamics governing the flight-path of an aircraft are in general highly nonlinear and involve complex physics for which no accurate models are available. In the past decades, some new nonlinear control design techniques appeared of interest for the development of improved control schemes for the flight-path tracking mode. In this communication, two nonlinear control techniques are used for the design of flight-path tracking control laws for a transport aircraft. A first control technique adopts a classical nonlinear dynamic inversion control scheme where enhanced robustness is introduced, and a second control scheme based on the backstepping technique is developed. These two approaches are compared in terms of applicability, complexity and robustness with respect to modeling inaccuracies and external perturbations. Finally, simulation results are displayed and discussed.

Nomenclature

V_T : true aircraft speed,

α : angle-of-attack, γ : vertical path angle, θ : pitch angle,

q pitch angular rate,

δ_e : elevator setting,

L, T : lift and thrust forces,

M : pitch moment, I_y : y-axis inertial moment,

ρ : air density, \bar{c} : mean wing chord, S : reference area,

$C_{L_0}, C_{L_\alpha}, C_{L_\delta}, C_{m_0}, C_{m_\alpha}, C_{m_\delta}, C_{m_q}, C_{m_\dot{\alpha}}$: non-dimensional aerodynamic parameters,

m : aircraft mass, g : gravitational acceleration

Introduction

The application of nonlinear control techniques to flight control problems has persistently drawn considerable attention in the past several decades [1] [2]. More recently, systematical analysis tools have been developed to enhance their applicability. Nonlinear dynamics inversion control is already a popular nonlinear technique used to tackle flight control problems. In the last two decades, the nonlinear dynamics inversion control approach has been well established in theory and has drawn considerable attention for its applications to flight control problems. This technique avoids the tedious gain scheduling problem and the constrained stability for small maneuvers as well. Due to the principle of dynamics inversion involving canceling the nonlinearities, it strongly relies on rather precise nonlinear models. This may produce limited performance when applied to systems with only approximate empirical nonlinear models. Some research works have introduced the use of neural networks to build up accurate numerical models over a region of interest. Contrarily to the nonlinearities cancelling approach of nonlinear dynamics inversion technique, the backstepping technique intends to take advantage of the

⁴ Researcher

nonlinearities and this mainly to guarantee the global stability of the controlled system dynamics. It appears specially suited to quite common cascaded forms. Its extensions to adaptive control and its integration with other nonlinear control techniques seem to enhance its robustness and to broaden its field of application.

The main aim of this paper is to assess the respective performances of the nonlinear dynamic inversion technique and of the backstepping technique applied to the flight-path tracking control problem.

First, control law synthesis based on the nonlinear dynamic inversion and the backstepping techniques is briefly introduced. Then the flight path dynamics for a transportation aircraft are displayed. Following the detailed flight-path tracking control law synthesis from both techniques are displayed. Then respective simulation results are provided and their performances are compared.

Nonlinear Dynamic Inversion

The basic idea of nonlinear dynamic inversion [3] [4] [5] is to transform a nonlinear dynamic system into an equivalent controllable linear system through a change of coordinates by compensating the nonlinear parts of system dynamics. This leads to adopt as control objective a stable linear dynamics for the output error. A nonlinear state feedback control law is then derived when a non singularity condition is satisfied.

Consider an affine dynamic system given by:

$$\dot{x} = f(x) + \sum_{i=1}^m g_i(x)u_i \quad (1a)$$

$$y = h(x) \quad (1b)$$

where $x \in \mathbf{R}^n$, $u \in \mathbf{R}^m$, $y \in \mathbf{R}^m$, and f , g and h are smooth vector fields of x . The system has relative degrees r_i ($\sum_{i=1}^m r_i \leq n$, $i = 1, \dots, m$) around the point x_0 corresponding to the outputs y_i at x_0 such that

$$\begin{pmatrix} y_1^{(r_1)} \\ \vdots \\ y_m^{(r_m)} \end{pmatrix} = A(x) + B(x)u \quad (2)$$

If $B(x)_{m \times m}$ is nonsingular, the resulted feedback control law can be therefore obtained:

$$u = B^{-1}(x)(v - A(x)) \quad (3)$$

where new control input $v = [v_1, \dots, v_m]^T$ can be chosen by

$$v_i = y_d^{(r_i)} - \sum_{k=0}^{r_i-1} c_{ik} (y_i^{(k)} - y_{di}^{(k)}) \quad (4)$$

where y_{di} is the reference control input for the output dynamics. The tracking error is given by

$$e_i = y_i - y_{di} \quad (5)$$

whose dynamics is given by :

$$e_i^{(r_i)} + c_{ir_i-1} e_i^{(r_i-1)} + \dots + c_{i1} e_i^{(1)} + c_{i0} e_i = 0 \quad (6)$$

where the coefficients c_{ik} can be chosen to make the output dynamics asymptotically stable and ensure the tracking of output y_i towards the reference output y_{di} . However the derived feedback control law works only if no internal dynamics ($\sum_{i=1}^m r_i = n$) are present or its internal dynamics are stable ($\sum_{i=1}^m r_i < n$).

Backstepping

Consider a dynamic system

$$\dot{x}_1 = f(x_1) + g(x_1)x_2 \quad (7a)$$

$$\dot{x}_2 = u \quad (7b)$$

where $x_1 \in \mathbf{R}$, $x_2 \in \mathbf{R}$ are state variables and $u \in \mathbf{R}$ is the control input.

The control objective [6] [7] [8] to this dynamic system is to design a control law such that the state x_1 can be stabilized at 0, a supposed global asymptotically stable equilibrium with null input

$(f(0) = 0)$. Furthermore, it can be observed that x_2 can be regarded as a virtual (or mediate) control input for the dynamics x_1 , and the dynamics of x_2 is controlled by the real control input u . This is an important feature to make use of for the following control law synthesis. Now, suppose that there exists a control law:

$$x_2 = \xi(x_1) \quad (8)$$

such that the dynamics of x_1 can be stabilized at 0 while we can find a Lyapunov function $V_1(x_1)$ satisfy the condition

$$\dot{V}_1(x_1) = \frac{\partial V_1}{\partial x_1} (f(x_1) + g(x_1)\xi(x_1)) \leq -W_1(x_1) \quad (9)$$

where $W_1(x_1)$ is positive definite function. Then the whole dynamics can be expressed as:

$$\dot{x}_1 = f(x_1) + g(x_1)\xi(x_1) + g(x_1)z \quad (10a)$$

$$\dot{z} = w \quad (10b)$$

where

$$z = x_2 - \xi(x_1) \quad (11a)$$

$$w = u - \dot{\xi}(x_1) \quad (11b)$$

with

$$\dot{\xi}(x_1) = \frac{\partial \xi}{\partial x_1} (f(x_1) + g(x_1)x_2) \quad (12)$$

Then, the Lyapunov function candidate of the full system is given by:

$$V(x_1, z) = V_1(x_1) + \frac{1}{2}z^2 \quad (13)$$

The time derivative of $V(x, z)$ is given by:

$$\dot{V}(x_1, z) = \frac{\partial V_1}{\partial x_1} (f(x_1) + g(x_1)\xi) + \frac{\partial V_1}{\partial x_1} g(x_1)z + zw \quad (14)$$

Substituting the inequality of Eq.(9) and Eq.(10) into Eq.(14) yields:

$$\dot{V}(x_1, z) \leq -W_1(x_1) + \frac{\partial V_1}{\partial x_1} g(x_1)z + zw \quad (15)$$

By an adequate choice of w , such as:

$$w = -\frac{\partial V_1}{\partial x_1} g(x_1) - kz \quad (16)$$

where k is a positive constant, the full system is globally asymptotically stable since it satisfies the following condition:

$$\dot{V}(x_1, z) \leq -W_1(x_1) - kz^2 \quad (17)$$

Finally, substituting Eq.(7) and Eq.(11) into Eq.(16) yields the effective control input:

$$u = \frac{\partial \xi}{\partial x_1} (f(x_1) + g(x_1)x_2) - \frac{\partial V_1}{\partial x_1} g(x_1) - k(x_2 - \xi(x_1)) \quad (18)$$

Dynamics Equations

In general, the flight path angle of an aircraft is defined as:

$$\gamma = \sin^{-1} \left(\frac{\dot{h}}{V_T} \right) \quad (19)$$

where \dot{h} and V_T respectively represent the change rate of altitude change and the true airspeed. Restricting the aircraft dynamics to the vertical plane, additional assumptions of non-rolling motion (roll angle: $\psi=0$) and negligible sideslip (sideslip angle: $\beta = 0$) are done. Then:

$$\gamma = \theta - \alpha \quad (20a)$$

$$\dot{\theta} = q \quad (20b)$$

$$q_W = q \quad (20c)$$

where θ , α , q and q_W is respectively the pitch angle, the angle-of-attack, the pitch rate in body-axes, and the pitch rate in wind-axis. The transport aircraft in general operates at low angle-of-attack such that:

$$\sin \alpha \approx \alpha \quad (21)$$

The time-derivative of the flight path angle is therefore approximated by:

$$\dot{\gamma} = -\frac{g}{V_T} \cos \gamma + \frac{L}{m V_T} \quad (22)$$

where V_T is the airspeed of aircraft; L is the lift; m and g are the mass and the gravitational acceleration respectively. The relevant dynamic equations of α and θ are given by:

$$\dot{\alpha} = -\frac{1}{m V_T} (L - mg \cos \gamma) + q \quad (23a)$$

$$\dot{q} = \frac{M}{I_y} \quad (23b)$$

where M is the pitching moment and I_y is the inertial moment about y axis in body-axes. The aerodynamic force and moment can be expressed as:

$$L = \frac{\rho V_T^2 S}{2} (C_{L_0} + C_{L_\alpha} \alpha + C_{L_\delta} \delta_e) \quad (24a)$$

$$M = \frac{\rho V_T^2 \bar{c}}{2} [C_{m_0} + C_{m_\alpha} \alpha + C_{m_\delta} \delta_e + \frac{c}{2V_T} (C_{m_q} q + C_{m_\dot{\alpha}} \dot{\alpha})] \quad (24b)$$

where ρ is the air density; \bar{c} is the mean wing chord length; δ_e is the deflection angle of elevator; $C_{L(*)}$ and $C_{m(*)}$ are the lift coefficients and the pitching moment coefficients respectively from different contributions.

Control Law Synthesis

Nonlinear dynamic Inversion

In this study, the system to be controlled is considered as a SISO system: the flight-path angle (γ) is the output while the input is the deflection of the elevator (δ_e). The airspeed V_T and the thrust T are assumed to remain constant while flaps adopt a fixed position. From Eq.(22) - Eq.(23), the state and output of aircraft dynamics can be chosen such as:

$$S : \begin{cases} x = (\gamma, \alpha, q)^T \\ u = \delta_e \\ y = \gamma \end{cases} \quad (25)$$

where x , u , y respectively denote the entire state, the control input and the output of the system.

By differentiating the output until the input appears, it is obvious that the control input (δ_e) appears in the first time-derivative of the output (γ) such that its relative degree equals to 1 so that second order unobservable internal dynamics is present. This internal dynamics includes the fast dynamics of pitching rate. At this stage, the direct implementation of dynamic inversion technique may not work due to this internal dynamics. In order to overcome this internal dynamics, the input can be changed to elevator rate reference value so that the differentiating process can be pursued. Differentiating again the output yields:

$$\ddot{\gamma} = \frac{g}{V_T} \dot{\gamma} \sin \gamma + \frac{\rho V_T S}{2m} (C_{L_\alpha} \dot{\alpha} + C_{L_\delta} \dot{\delta}_e) \quad (26)$$

For further simplicity, assume:

$$\sin \gamma = \gamma \text{ and } \dot{\alpha} = q - \dot{\gamma} \quad (27)$$

such that:

$$\ddot{\gamma} = \frac{g}{V_T} \dot{\gamma} \gamma + \frac{\rho V_T S}{2m} [C_{L_\alpha} (q - \dot{\gamma}) + C_{L_\delta} \dot{\delta}_e] \quad (28)$$

Since at this stage internal dynamics are not eliminated, another differentiation appears necessary. Considering that the elevator dynamics obeys to the first order relation:

$$\ddot{\delta}_e = \frac{1}{\tau_E} (\dot{\delta}_{ec} - \dot{\delta}_e) \quad (29)$$

where $\dot{\delta}_{ec}$ is the control signal, it is feasible to consider an additional differentiation. This gives:

$$\gamma^{(3)} = \frac{g}{V_T} (\ddot{\gamma} \gamma + \dot{\gamma}^2) + \frac{\rho V_T S}{2m} [C_{L_\alpha} (\dot{q} - \ddot{\gamma}) + C_{L_\delta} \ddot{\delta}_e] \quad (30)$$

Then the nonsingular condition reduces here to:

$$\frac{\rho V_T S}{2m} C_{L_\delta} \neq 0 \quad (31)$$

which is satisfied, although C_{L_δ} may be very small.

Here it is supposed that the path-angle control objective is to follow a given trajectory γ_d in such a way that output error is stable and obeys the third order linear dynamics:

$$(\gamma^{(3)} - \gamma_d^{(3)}) + c_2(\ddot{\gamma} - \ddot{\gamma}_d) + c_1(\dot{\gamma} - \dot{\gamma}_d) + c_0(\gamma - \gamma_d) = 0 \quad (32)$$

$$\begin{aligned} \dot{\delta}_{ec} = & \dot{\delta}_e + \frac{\tau_e m V_T}{C_{L_\delta}} \left\{ \frac{g}{V_T} (\dot{\gamma})^2 + \left(\frac{g}{V_T} \gamma - \frac{1}{m V_T} \left(\frac{1}{2} \rho V_T^2 S C_{L_\alpha} \right) \right) \ddot{\gamma} \right. \\ & + \frac{1}{m V_T} \left(\left(\frac{1}{2} \rho V_T^2 S C_{L_\alpha} \right) \frac{M}{I_y} \right) \\ & \left. + \gamma_d^{(3)} - c_2(\ddot{\gamma} - \ddot{\gamma}_d) - c_1(\dot{\gamma} - \dot{\gamma}_d) - c_0(\gamma - \gamma_d) \right\} \end{aligned} \quad (33)$$

Observe that, since the actuator dynamics have been introduced, internal dynamics, related with the angle of attack, remains with a risk of instability. Observe also that to implement this control law it is necessary to get accurate estimates of the current pitch moment.

Another possible approach to implement the nonlinear inversion technique is to adopt simplified aerodynamic models and introduce a corrective term. Then, considering only the main aerodynamic effects, relations (24a) and (24b) become:

$$L \approx \frac{\rho V_T^2 S}{2} (C_{L_0} + C_{L_\alpha} \alpha) \quad (24a')$$

$$M \approx \frac{\rho V_T^2 S}{2} [C_{m_0} + C_{m_\alpha} \alpha] \quad (24b')$$

Relation (28) becomes:

$$\ddot{\gamma} = \frac{g}{V_T} \dot{\gamma} + \frac{\rho V_T S}{2m} [C_{L_\alpha} (q - \dot{\gamma})] \quad (28')$$

and relation (30) becomes:

$$\gamma^{(3)} = \frac{g}{V_T} (\ddot{\gamma} \dot{\gamma} + \dot{\gamma}^2) + \frac{\rho V_T S}{2m} [C_{L_\alpha} (q - \dot{\gamma})] \quad (30')$$

The new control law is given by:

$$\begin{aligned} \delta_e = & \frac{C_{m_0} + C_{m_\alpha} \alpha}{C_{m_\delta}} + \left\{ \frac{4mI_y}{C_{m_\delta} (\rho V_T^2 S)^2} \right\} \left\{ \frac{g}{V_T} (\ddot{\gamma} \dot{\gamma} + \dot{\gamma}^2) + \right. \\ & \left. + \gamma_d^{(3)} - c_2(\ddot{\gamma} - \ddot{\gamma}_d) - c_1(\dot{\gamma} - \dot{\gamma}_d) - c_0(\gamma - \gamma_d) \right\} \end{aligned} \quad (33')$$

However, since in this case important simplifications have been adopted to avoid the appearance of internal dynamics, it appears convenient to introduce an integral corrective term to get a control law such as:

$$\delta_{ec} = \delta_{ec} - c_3 \left\{ \frac{4mI_y}{C_{m_\delta} (\rho V_T^2 S)^2} \int_0^t (\gamma - \gamma_d) d\tau \right\} \quad (33'')$$

So it appears that, whatever the approach chosen, the nonlinear inversion technique leads to foreseeable difficulties. They will be displayed through simulations in the case of the path angle control of an F16.

Application of backstepping to flight-path angle control

As considered earlier, the lift contributed from the deflection of elevator is relatively small in comparison with the contribution from the angle-of-attack ($C_{L_\delta} \leq 10\% C_{L_\alpha}$). When the term of the deflection of elevator is neglected, the dynamics of flight-path angle are written as:

$$\begin{aligned} \dot{\gamma} \approx & -\frac{g}{V_T} \cos \gamma + \frac{L}{m V_T} \\ = & \Gamma(m, V, \alpha, \gamma) \end{aligned} \quad (34)$$

The first step of a backstepping approach consists in defining the output error which is given here by:

$$z_\gamma = \gamma - \gamma_d \quad (35)$$

where γ_d is the desired flight-path angle. Then the error dynamics of flight-path angle is given by:

$$\dot{z}_\gamma = \Gamma(m, V, \alpha, \gamma) \quad (36)$$

A Lyapunov function for γ is given by:

$$V_\gamma = \frac{1}{2}z_\gamma^2 \quad (37)$$

Its time-derivative is then given by

$$\begin{aligned}\dot{V}_\gamma &= z_\gamma \Gamma(m, V, T, \alpha, \gamma) \\ &= z_\gamma \Gamma(m, V, T, \theta - \gamma_c - z_\gamma, \gamma_c + z_\gamma)\end{aligned}\quad (38)$$

where it is possible to choose a proper θ_c for θ such as:

$$\theta_c = \gamma + \lambda_\gamma z_\gamma + \mu_\gamma \int z_\gamma d\tau \text{ with } \lambda_\gamma < 1 \quad (39)$$

which makes the dynamics of γ asymptotically stable since z_γ obeys approximately to equation:

$$\ddot{z}_\gamma - \left(\frac{\rho V_T^2 S C_{L_\alpha}}{2} \right) (\lambda_\gamma \dot{z}_\gamma + \mu_\gamma z_\gamma) \approx 0 \quad (40)$$

such that:

$$\dot{V}_\gamma = \Gamma(m, V, T, (\lambda_\gamma - 1)z_\gamma + \mu_\gamma \int z_\gamma d\tau, \gamma_c + z_\gamma) < 0 \quad (40)$$

At the second step, the dynamics of pitch angle θ evidently are related to the pitching rate q by Eq.(20b). The pitch dynamics here is assumed to be first order:

$$q_c = \frac{\theta - \theta_c}{\tau_\theta} \quad (41)$$

where τ_θ is a time constant.

At the third step, a connection is built between the pitching rate and the deflection of elevator δ_e by using the dynamic equation of pitching moment which is here the source of most modeling errors.

By defining the error dynamics of q such as:

$$z_q = q - q_c \quad (42)$$

A Lyapunov function for q can be chosen such as

$$V_q = V_\gamma + \frac{1}{2}z_q^2 \quad (43)$$

Using Eq.(39), Eq.(41) and Eq.(42) in Eq.(43) gives:

$$V_q = V_\gamma + \frac{1}{2} \left(q - \frac{\gamma_c - (\lambda_\gamma z_\gamma + \mu_\gamma \int z_\gamma d\tau)}{\tau_\theta} \right)^2 \quad (42)$$

Its time derivative is given by:

$$\dot{V}_q = \dot{V}_\gamma + \left(q - \frac{\gamma_c - \lambda_\gamma z_\gamma - \mu_\gamma \int z_\gamma d\tau}{\tau_\theta} \right) \left(\frac{M}{I_y} + \frac{\lambda_\gamma}{\tau_\theta} \Gamma(m, V_T, \alpha, \gamma) \right) \quad (43)$$

where a proper δ_e can be chosen such as:

$$\frac{M}{I_y} = \frac{\lambda_\gamma}{\tau_\theta} \Gamma(m, V, T, \alpha, \gamma) - \mu \left(q - \frac{\gamma_c - \lambda_\gamma z_\gamma - \mu_\gamma \int z_\gamma d\tau}{\tau_\theta} \right) \quad (44)$$

where μ is a positive parameter.

The pitching dynamics are then stabilized since they satisfy the following condition:

$$\dot{V}_q < 0 \quad (45)$$

since:

$$\dot{V}_q = \dot{V}_\gamma - \mu \left(q - \frac{\gamma_c - \lambda_\gamma z_\gamma - \mu_\gamma \int z_\gamma d\tau}{\tau_\theta} \right)^2 \quad (46)$$

By substituting Eq.(23) and Eq.(24) into Eq.(38) we can finally derive the Backstepping control law:

$$\begin{aligned}\delta_e &= \frac{-2I_y}{\rho V_T^2 S C_{m_\delta}} [\lambda_\gamma \Gamma(m, V_T, \alpha, \gamma) + \mu \left(q - \frac{\gamma_c - \lambda_\gamma z_\gamma - \mu_\gamma \int z_\gamma d\tau}{\tau_\theta} \right)] \\ &\quad - \frac{1}{C_{m_\delta}} [C_{m_0} + C_{m_\alpha} \alpha + \frac{c}{2V_T} (C_{m_q} q + C_{m_\alpha} \dot{q})]\end{aligned}\quad (46)$$

It appears that the backstepping approach is far from being straightforward and that such an intricate construction should be tested through fully to provide confidence in its performances.

Simulation Results

A general 6-DOF nonlinear dynamics of the F-16 combat aircraft including the first-order

dynamics of actuators and propulsion model is used for simulation [1]. In order to compare the robustness of both path angle control techniques, a rough PID airspeed controller is implemented to maintain speed around a reference value. The F-16 is assumed to fly at a speed of 500 ft/s with initial altitude of 20000 ft.

It appears necessary to tune the controller gains with a trial-and-error process to obtain an acceptable tracking performance.

Figure 1 and figure 2 show the tracking performance of flight-path angle and relevant data when using the proposed modified nonlinear dynamic inversion technique while the airspeed controller is engaged. However, the airspeed changes during the engagement of the control input. This results in a degradation of the tracking performance. The case shown in figure 3 and figure 4 is performed without the airspeed controller engaged such as to severely affect the tracking performance while the airspeed changes autonomously with the fixed thrust.

Figures 5-8 display the tracking performance obtained using the backstepping control technique. The response appears to be smoother than the one obtained with the nonlinear dynamic inversion technique.

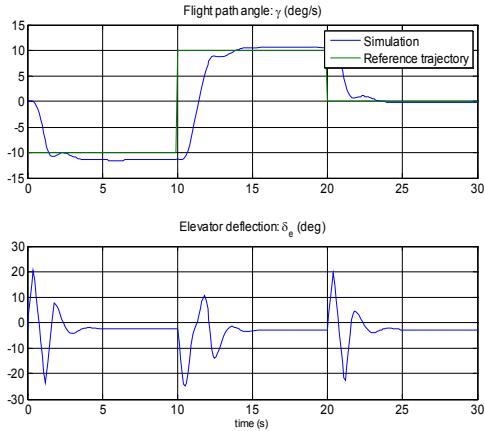

Figure 1. NLI path angle control with airspeed regulation

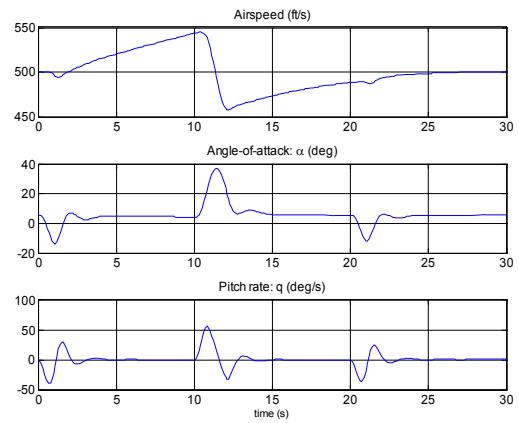

Figure 1. NLI path angle control with airspeed regulation

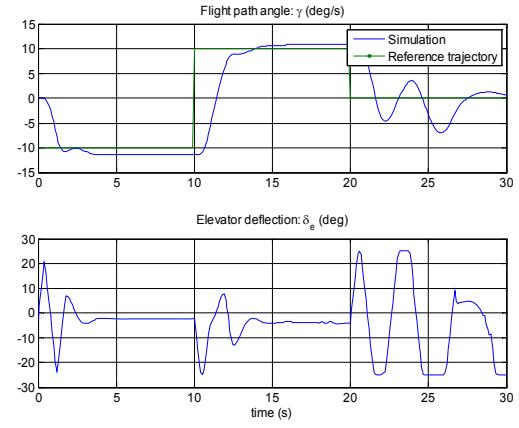

Figure 3. NLI path angle control without airspeed regulation

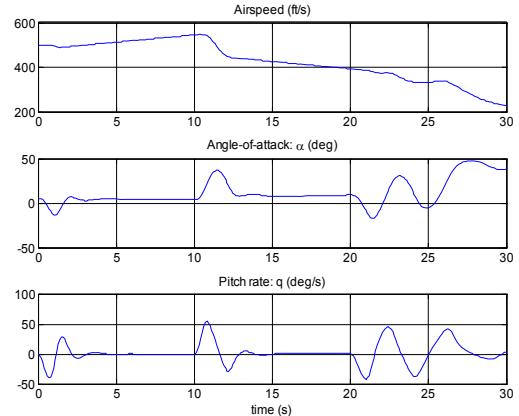

Figure 4. NLI path angle control without airspeed regulation

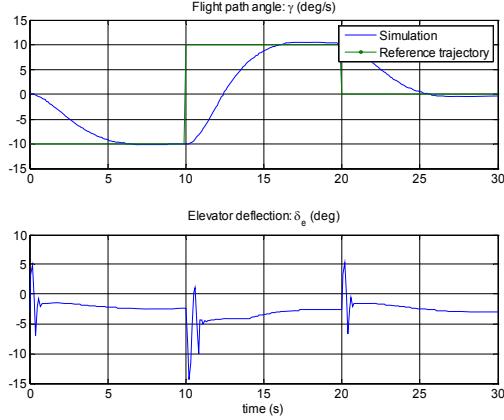

Figure 5. Backstepping path angle control without airspeed regulation

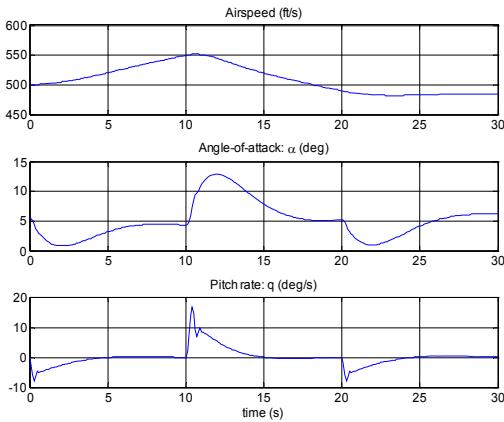

Figure 6. Backstepping path angle control without airspeed regulation

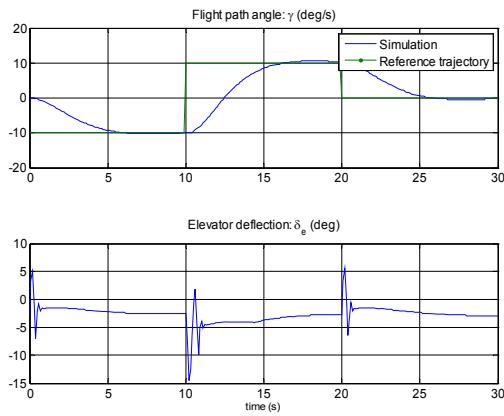

Figure 7. Backstepping path angle control with airspeed regulation

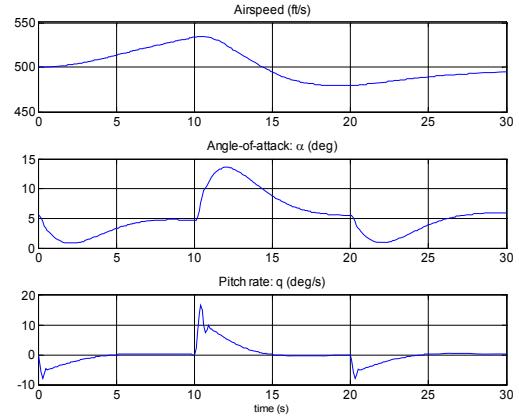

Figure 8. Backstepping path angle control with airspeed regulation

It appears that the results obtained with the backstepping technique are more robust to airspeed variations. This technique presents also more tuning parameters related with the successive Lyapunov functions used to secure the global stability of the controlled system.

Conclusion

In this paper the problem of path angle control design for an aircraft has been considered. Two popular non linear control techniques have been introduced and applied to this control problem: nonlinear dynamics inverse control and backstepping.

In the case of non linear dynamics inverse control, it appears that the choice of the longitudinal dynamics model which is used in the inversion, is critical to avoid the presence of uncontrolled internal dynamics. This choice may lead, when important simplifying assumptions are made, to the introduction of an integral term to improve the accuracy of the path angle tracking.

Also, it appears that the application of the backstepping technique is not straightforward and that the resulting complex control structure must be intensively tested to provide confidence in its performances. Indeed, the stability of the control scheme is here no more guaranteed in theoretical grounds considering the assumptions which have been necessary to be done to apply this multilevel control scheme.
